## Distance Weighted Discrimination

## Adam Rahman

November 27, 2024

Given two sets of points in a matrix  $\mathbf{X} \in \mathcal{R}^n$  with associated class variables [-1,1] in  $\mathbf{Y} = diag(\mathbf{y})$ , distance weighted discrimination ([1]) seeks to classify the points into two distinct subsets by finding a hyperplane between the two sets of points. Mathematically, the distance weighted discrimination problem seeks a hyperplane defined by a normal vector,  $\boldsymbol{\omega}$ , and position,  $\boldsymbol{\beta}$ , such that each element in the residual vector  $\bar{\mathbf{r}} = \mathbf{Y}\mathbf{X}^{\mathsf{T}}\boldsymbol{\omega} + \beta\mathbf{y}$  is positive and large. Since the class labels are either 1 or -1, having the residuals be positive is equivalent to having the points on the proper side of the hyperplane.

Of course, it may be impossible to have a perfect separation of points using a linear hyperplane, so an error term  $\xi$  is introduced. Thus, the perturbed residuals are defined to be

$$\mathbf{r} = \mathbf{Y}\mathbf{X}^\mathsf{T}\boldsymbol{\omega} + \beta\mathbf{y} + \boldsymbol{\xi}$$

Distance Weighted Discrimination solves the following optimization problem to find the optimal hyperplane[1].

$$\begin{array}{ll} \underset{\mathbf{r}, \ \boldsymbol{\omega}, \ \boldsymbol{\beta}, \ \boldsymbol{\xi}}{\text{minimize}} & \sum_{i=1}^{n} (1/r_i) + C \mathbf{1}^\mathsf{T} \boldsymbol{\xi} \\ \text{subject to} & \\ \mathbf{r} & = \mathbf{Y} \mathbf{X}^\mathsf{T} \boldsymbol{\omega} + \beta \mathbf{y} + \boldsymbol{\xi} \\ \boldsymbol{\omega}^\mathsf{T} \boldsymbol{\omega} & \leq 1 \\ \mathbf{r} & \geq \mathbf{0} \\ \boldsymbol{\xi} & \geq \mathbf{0} \\ \end{array}$$

where C > 0 is a penalty parameter to be chosen.

The function dwd takes as input two  $n \times p$  matrices X1 and X2 containing the points to be separated, as well as a penalty term  $C \ge 0$  penalizing the movement of a point on the wrong side of the hyperplane to the proper side, and returns the optimal solution using sqlp to the distance weighted discrimination problem.

## Numerical Example

Consider two point configurations - An and Ap - which we would like to classify using distance weighted discrimination. Each point configuration is a matrix containing 50 points in three dimensional space.

- R> data(Andwd)
  R> data(Apdwd)
  R> d <- ncol(Andwd)
  R> head(Andwd)
- V1 V2 V3
  [1,] 0.214 -1.577 -1.525

```
[2,] 0.480 0.624 -0.501
[3,] 0.088 0.330 -1.213
[4,] 0.444 -0.398 -0.630
[5,] -0.363 -1.081 -1.447
[6,] 0.123 -0.077 -0.167

R> head(Apdwd)

V1 V2 V3
[1,] 0.687 0.102 0.726
```

```
V1 V2 V3
[1,] -0.687 0.192 0.726
[2,] 0.444 0.782 0.887
[3,] 2.360 -1.114 0.089
[4,] 2.230 1.428 1.369
[5,] 1.555 -0.142 2.138
[6,] 0.259 0.163 1.818
```

Distance weighed discrimination is used to separate these two configurations by specifying an appropriate penalization term. Here, we will take a value of 0.5.

```
R> out <- dwd(Apdwd, Andwd, 0.5)
```

The information defining the seperating hyperplane ( $\omega$  and  $\beta$ ) is stored in the X output vector.
